**Coast Range Ophiolite near Stonyford, Northern California:
Evidence for Normal Faulting**

by

Scott Henry Hoag, B.S.

THESIS

Presented to the Faculty of the Graduate School of
The University of Texas at Austin
in Partial Fulfillment
of the Requirements
for the Degree of

Master of Science in Geological Sciences

**The University of Texas at Austin
May, 2012**

The Thesis committee for Scott Henry Hoag

Certifies that this is the approved version of the following thesis

**Coast Range Ophiolite near Stonyford, Northern California:
Evidence for Normal Faulting**

**Approved by
Supervising Committee:**

Supervisor: _____
Mark Cloos

Randall Marrett

Jaime Barnes

Acknowledgements

One thing I have learned in life is that very few goals can be accomplished without the help of others. I would like to first thank my supervisor Mark Cloos. He saw my potential and took me on as a student even though my geology background was limited. He taught me how to be a scientist and through his guidance gave me the confidence to push my limits and accomplish the mission. His leadership is greatly appreciated.

I would like to extend gratitude to my other committee members Randy Marrett and Jaime Barnes. Their technical insight and feedback was critical to the direction and completion of this project.

I would like to give thanks to my field assistant Yomi Olufowoshe. He had a positive attitude throughout our field experience. Through his hard work he helped make it possible for us to finish the work in a timely manner. I would also like to thank David Isle, George Pendell and the Stonyford town's people for their interest in Geology and their willingness to help out in any way possible to make our stay enjoyable.

To the Mark Cloos research group that I worked with, including Ethan Lake, Marin Trautman, and Win Wharton I want to thank you for the discussions, the help, and the laughs through the ups and downs of graduate school.

For all the staff that makes things work behind the scenes so we can focus on science, I am thankful. Specifically I would like to thank Philip Guerrero, Dennis Trombatore and the Walter Library staff, Ty Lehman, Adrian Huh, and Jeffrey Horowitz.

Lastly, I would like to thank my family. Graduate school is a trying time in one's life. My wife Kelly was there with me every step of the way and her love and support was an inspiration. My two sons Tris and Max kept me focused and my in-laws Bill and Maureen gave my wife much needed help.

Abstract

Coast Range Ophiolite near Stonyford, Northern California: Evidence for Normal Faulting

Scott Henry Hoag, M.S. Geo. Sci.

The University of Texas at Austin, 2012

Supervisor: Mark Cloos

The Franciscan Complex and Coast Range Ophiolite (CRO) are juxtaposed along the Coast Range Fault (CRF), which is steeply dipping to near vertical in the Stonyford area. The CRF has been interpreted as a thrust fault and a normal fault but no kinematic data has been presented for the Stonyford region.

The CRO locally is internally disrupted and can be described as an ophiolitic *mélange*. Near Stonyford, serpentinites are in contact with Great Valley sediments to the east and with Franciscan rocks to the west. Mafic volcanics are only found at a few localities with some chert and gabbros. Massive serpentinites form most of the southernmost transect while foliated serpentinite *mélange* dominates the northern transects.

Six structural geologic transects were made in the CRO along National Forest Service roads in the Mendocino National Forest near the Stonyford,

California area. Data were collected from 21 road cuts totaling approximately 10 kilometers of CRO exposure. Exposures were typically two meters high with the main exception along Goat Mountain Road where the serpentinite was massive with outcrop heights of 10 to 20 meters. Fault plane orientations and sense of slip (where recognizable) were measured for all faults traceable for more than 10 cm. A total of 1,108 faults were measured, 414 contained lineations, and 326 had lineations with steps which determine sense of slip. Approximately two-thirds of the faults with full kinematics had evidence for normal offset. About 25% recorded reverse offset, mostly steeply dipping surfaces. Strike-slip faulting, both right and left-lateral, accounted for 10% of the data.

The ascent of the Franciscan and CRO, and upturning of the Knoxville Formation (Great Valley Group) to near vertical attitude was mostly a result of normal faulting. The Great Valley Group strata, with little internal offset by faulting, indicates the disruption of the CRO near Stonyford predates most of the normal faulting. This is consistent with pre-subduction deformation of the CRO in an oceanic fracture zone.

CHAPTER 1: INTRODUCTION

Three lithotectonic belts are exposed near Stonyford: the Franciscan Complex, the Coast Range Ophiolite, and the Great Valley Group. Subducted Franciscan sediments were underplated beneath the Coast Range Ophiolite at 15-20 km depth, reaching lawsonite-bearing blueschist facies metamorphism. The Coast Range Ophiolite is a section of oceanic crust and serpentinized upper mantle at the leading edge of the North American Plate. The ophiolitic rocks have reached the surface from a range of depths of at least three kilometers to as much as 15 km. Tectonic models have been presented for the Franciscan Complex/Coast Range Ophiolite/Great Valley Group to explain the contact relationships exposed in northern California. These models are based on field observations only and typically do not present supporting structural field data. This study adds fault data from six transects within the Coast Range Ophiolite near Stonyford, California. The structural data will be used to analyze existing tectonic models and to generate a preferred model for the Stonyford area. This model will explain how blueschist facies rocks are exposed at the surface juxtaposed with ophiolitic rocks and forearc sediments. No previous studies have collected structural data from this area.

1.1 Geologic Setting

More than 10,000 km of the east-dipping Farallon Plate subducted beneath the North American Plate since the late Jurassic (Ernst, 1984). The Franciscan Complex, the Great Valley Group, and the Sierra Nevada Batholith comprise the three major lithotectonic belts (Figure 1.1) formed during subduction (Figure 1.2b). The Franciscan Complex is an accretionary prism, the Great Valley Group is comprised of forearc basin strata deposited on an ophiolitic basement, and the Sierra Nevada Batholith is the eroded

Figure 1.1. Geologic map of California showing extent of the three major subduction zone lithotectonic belts, San Andreas Fault Zone, the Mendocino Triple Junction, and active subduction and volcanism. After U.S. Geologic Survey and California Division of Mines and Geology (1966). Study area located with black box.

Figure 1.2. (a) Map of Northern California showing the subduction related lithotectonic belts. A to A' indicates a subduction zone cross-section line. B to B' indicates a Franciscan Complex cross-section line. Study area is located within the box. plutonic root of the volcanic arc (Figure 1.2a). Active subduction ended about 2 million years ago at the latitude of Stonyford, California as the Mendocino Triple Junction moved north changing the tectonic regime to right-lateral strike-slip motion along the San Andreas Fault (Atwater, 1970).

The Great Valley forearc basin strata (Knoxville Formation) overlie serpentinitized ophiolitic basement in fault contact with lawsonite-bearing blueschist grade metamorphic rocks of the Franciscan Complex (Raney, 1976). Several tectonic models have been proposed to explain the contact relationship: reverse-type fault (Ernst, 1970; Suppe, 1979; Wentworth et al., 1984; see Table 1.1), strike-slip-type fault (McLaughlin et al., 1988; see Table 1.2), a normal-type fault (Platt, 1986; Harms et al., 1992; see Table 1.3), or a combination (Wakabayashi and Unruh, 1995; see Table 1.4). Four studies, Ring and Brandon (1994), and Huot and Maury (2002), Perri (2005), and Dewhurst (2008) have collected fault data within the Coast Range Ophiolite north of San Francisco but none in the Stonyford area. This study contributes an analysis of fault data collected from the Coast Range Ophiolite near Stonyford to help constrain the tectonic models for the uplift of the Franciscan Complex, the Coast Range Ophiolite, and the Great Valley Group.

1.1.1 The Great Valley Group

The Great Valley Group of northern and central California evolved as a late Mesozoic to early Cenozoic forearc basin. Strata record a transition from deep sea basin plane sediments during late Jurassic to migrating submarine fans in the Cretaceous to slope and shelf deposition in the Paleogene. The basin enlarged and eventually was supplied by large volumes of sediment from the Sierra Nevada magmatic arc (Ingersoll, 1982). The lowermost Great Valley Group sedimentary sequence exposed in the Stonyford area is the late Jurassic age Knoxville Formation (Figure 1.3). As first described by Taliaferro

(1943), the Knoxville Formation is four to five kilometers in thickness, mostly dark clay shales, with some sandstones and channelized conglomerates. He also reported the presence of detrital serpentine in the lowermost part of the Knoxville. The Knoxville Formation is exposed near Stonyford and is steeply dipping to the east. The continuity of the upturned strata is evident in air photos.

1.1.2 The Coast Range Ophiolite

North of Stonyford, California the Coast Range Ophiolite forms a mostly north-south trending, nearly continuous band of mafic and ultramafic rocks for approximately 80 kilometers. In the Stonyford area the Coast Range Ophiolite makes an acute bend (Figure 1.3) to the west and then an obtuse bend to the south. The Coast Range Ophiolite is continuous from the obtuse bend for approximately 50 kilometers to the south.

Bailey et al. (1970), proposed the mafic and ultramafic rocks at the base of the Great Valley Group are a section of oceanic crust termed the Coast Range Ophiolite. Oceanic crust is approximately 7 ± 1 km thick (Figure 1.4) and the idealized section consists of pelagic sediments, mafic volcanic flows, sheeted dikes/sills, massive gabbros, layered gabbros, layered peridotites, all overlying tectonized harzburgite. However, a complete idealized section of the Coast Range Ophiolite does not exist. In the Stonyford area, the ophiolite consists of small weathered outcrops of foliated or massive serpentinite. The best exposures are along the Goat Mountain and the Fouts Springs roads. The Goat Mountain Road Transect exposures are exceptional, forming a nearly continuous three kilometer long, 15-25 meter high outcrop of mostly massive serpentinite.

West of Stonyford, the area inside the bend in the ophiolite, is defined as the Stonyford Volcanic Complex by Shervais et al. (2005). This area consists mostly of mafic rocks with small blocks of radiolarian chert, sections

Figure 1.3. Geologic map of the Stonyford, California area with all major units represented. Location of the Coast Range Fault inferred with red dashed line. Acute and obtuse bends in fault indicated on map (discussion in Chapter 2).

Figure 1.4. Idealized oceanic crust and upper mantle. Shervais et al. (2005) reports gabbroic blocks near AukAuk Ridge (~1 km south of Black Diamond). Sediments and volcanic flows are found in the Stonyford Volcanic Complex. Serpentinite forms most exposures of the Coast Range Ophiolite in California.

of weathered pillow basalts, volcanoclastic breccias, small blocks of meta-plutonic rocks (diorite, gabbro, pyroxenite, wehlite), and volcanic glass. They collected samples from the Stonyford Volcanic Complex and the Coast Range Ophiolite. They conducted chemistry on the samples that are exposed in the field as mafics, including pillow basalts, gabbros, dikes and volcanic glass found at two localities within hyaloclastite breccias. ^{40}Ar - ^{39}Ar dates on volcanic glass from the hyaloclastite breccias range from 163.0 ± 0.7 Ma to 164.7 ± 0.8 Ma. They found the Stonyford Volcanic Complex to be of similar age to zircon crystallization ages from the Coast Range Ophiolite north of San Francisco, which ranged between 166 to 163 Ma. They believe the Coast Range Ophiolite/Stonyford Volcanic Complex formed in a suprasubduction zone setting. They conclude that a spreading center entered the subduction zone, becoming overridden by an actively extending forearc.

1.1.3 The Franciscan Complex

The Franciscan Complex (Figure 1.1) is most extensive north of the San Francisco Bay area where it forms three distinct units (Figure 1.2c): the Coastal, Central, and Eastern Belts (Bailey et al., 1964; Maxwell, 1974). The Coastal Belt is largely coherent, off-scraped strata. The Coastal Belt is mostly unmetamorphosed, consisting of bedded graywackes and shales that at most underwent burial metamorphism, only locally containing zeolite facies minerals (Bailey et al., 1964). The Central Belt can be mapped based on lithology and abundance of different types of blocks. The Central Belt is the *mélange* terrane within the Franciscan Complex, which contain rare blocks of eclogite and garnet-epidote bearing blueschist rocks (Maxwell, 1974) and graywacke blocks in a shale matrix (Hsu, 1968; Cloos, 1983). The Eastern Belt is underplated sediments that reached blueschist facies conditions (~20 km) during subduction metamorphism. It is mostly coherent and early

Cretaceous with U-Pb ages of detrital zircons as young as 144 to 123 Ma, and Ar-isotopic ages of metamorphism of ~121-117 Ma (Dumitru et al., 2010).

1.2 Coast Range Fault

The Coast Range Fault juxtaposes Franciscan Complex rocks in the footwall with Coast Range Ophiolite and the overlying Great Valley forearc sediments in the hanging wall (Ring and Brandon, 1994). The significance of this relationship has been extensively debated since the advent of plate tectonics. Several tectonic models have been used to explain the contact between the Franciscan Complex, Coast Range Ophiolite, and the Great Valley Group. Unfortunately, few of the models are based on direct kinematic measurements from exposed faults.

1.2.1 Pre-plate tectonics studies

The first geologists to study the Northern California Coast Ranges, Stanton (1895) and Fairbanks (1904) looked at the serpentinites and believed the contact with the Great Valley sediments was an unconformity. Taliaferro (1943) reexamined field relationships and concluded the serpentinites intruded into the Knoxville sediments which was deposited above the deformed Franciscan strata.

1.2.2 Reverse-type model studies

Jennings and Strand (1960) show the contact between Great Valley Sequence (now Group) and Coast Range Ophiolite as a major thrust fault on the geologic map of California. Bailey et al. (1964), Brown (1964), Irwin (1964), Dickinson (1966), Page (1966), Blake et al. (1967), and Brown (1968) all asserted that the Coast Range Ophiolite and the Franciscan Complex were thrust over the Great Valley Group.

With the advent of plate tectonics, Bailey and Blake (1969), Hamilton (1969), Ernst (1970), Page (1970), and Hsu (1971) concluded the Franciscan rocks were underthrust beneath the Coast Range Ophiolite and Great Valley

Group. Ernst (1970) interpreted the Coast Range thrust as the crustal expression of a late Mesozoic Benioff zone. He proposed a tectonic model that involved underthrusting of the Franciscan Complex beneath the Coast Range Ophiolite and the Great Valley. This provided a way to produce high-pressure, low-temperature blueschist facies rocks at depths of 20 km and greater.

Suppe (1979) proposed that the Franciscan/ Coast Range Ophiolite contact is repeated by a series of east dipping thrust sheets (Figure 1.5). He proposed the Great Valley Group was thrust over the Mesozoic Franciscan rocks, which are thrust over the Cenozoic Coastal Belt Franciscan rocks. His model explained why the Knoxville Formation is steeply dipping to the east and how slabs of ophiolite became emplaced over Franciscan rocks, but it does not explain why lawsonite-bearing blueschist (depth ~20 km) is exposed on the surface.

Wentworth et al. (1984) interpreted seismic reflection profiles as showing the east-dipping Coast Range Ophiolite and Great Valley strata were truncated above a west-dipping basement (Figure 1.6). They also believed seismic reflection images showed the Franciscan is wedged between the Coast Range Ophiolite and Great Valley Group. The wedge is bounded to the west by a west-dipping Coast Range thrust fault and to the east by a series of backthrusts.

Jachens et al. (1995) modeled the magnetic anomalies of central California to interpret the basement under the Coast Ranges (Figure 1.6). They proposed that the ophiolitic basement beneath the Great Valley Group also extends beneath the Franciscan Complex. They argued the Coast Range Fault was never a subduction zone thrust fault, but instead a roof

Figure 1.5. Reverse-type models with thrusting of Great Valley/Coast Range Ophiolite over Franciscan. (a) East-dipping décollement with Coast Range Fault as a thrust bending and folding the CRO over the Franciscan, simplified from Ring and Brandon (1994) after Ingersoll (1979), (b) East-dipping thin-skinned fold and thrust belt, simplified from Ring and Brandon (1994) after Suppe (1979).

Figure 1.6. Reverse-type models with Franciscan Complex underthrusting Great Valley/CRO with tectonic wedging. (a) CRO is wedged between a west-dipping Coast Range “thrust” and a series of east-dipping thrust sheets, modified from Constenius et al. (2000) after Wentworth et al. (1984). (b) Roof thrust above Franciscan wedge model, modified from Constenius et al. (2000) after Jachens et al. (1995).

thrust above an eastward wedge of Franciscan Complex beneath the ophiolitic basement capped by the Great Valley Group.

1.2.3 Normal-type model studies

Platt (1986) emphasized the fundamental problem of material formerly buried at depths greater than or equal to the thickness of continental crust is now at the surface. Subduction can bring material to great depths at relatively low temperatures beneath the upper plate. As the subducted material is underplated, an accretionary wedge thickens. He emphasized that shortening alone does not place buried rocks at the surface. Rock above must be removed or thinned to expose the high pressure rocks. He proposed when underplating thickens and oversteepens a wedge, internal extension by means of listric normal faulting occurs. The faults merge at depth into a ductile extensional zone that thins the rock mass. In this scenario, the Coast Range Fault is a major normal fault in a series of faults that brought lawsonite-bearing blueschist towards the surface, in juxtaposition with the Coast Range Ophiolite.

Jayko et al. (1987) postulated that the contact between the Franciscan and Coast Range Ophiolite was not the Coast Range “thrust” (Irwin, 1964; Bailey et al., 1970; Ingersoll and Dickinson, 1981). They interpreted faults in the Coast Ranges to be low-angle normal faults similar structurally to those in the Basin and Range province. Omission of structural section and displacement of younger over older (structurally higher over structurally lower strata) was cited as evidence for normal faulting.

Harms et al. (1992) believed that Franciscan extension occurred during subduction of an oceanic plate beneath the North American Plate (Figure 1.7). They concluded their model was similar to Platt’s (1986) extensional model, but differed by arguing for top-to-the east displacement that resulted in the western movement of the entire Franciscan Complex.

1.2.4 Hybrid-type model studies

Wakabayashi and Unruh (1995), Wakabayashi (1999), and Wakabayashi and Dilek (2003), discussed a model that incorporates the extension with respect to exhumation model presented by Platt (1986) with the tectonic wedging model presented by Wentworth et al. (1984) (Figure 1.8). High-pressure, low-temperature blueschists were brought to the surface by underplating and normal faulting with the same fault changing to reverse offset during late-stage contraction.

1.2.5 Strike-slip-type model studies

McLaughlin et al. (1988) proposed that the Coast Range Ophiolite formed in a forearc or back arc setting at equatorial latitudes between 169-163 Ma. They believed that rifting began in a backarc setting approximately 150 Ma. On a fast moving plate the rifted back arc moved northward from equatorial latitudes to mid-latitudes. The ophiolite was then displaced from the west side of the Great Valley and placed into the Franciscan along steeply dipping to low angle reverse faults. Additionally, they believed an ophiolite in western Washington correlates with the Coast Range Ophiolite, indicating a lateral displacement of 950 to 1200 km. They believe translation was initiated between 90 and 60 Ma and corresponds to northward component of relative motion between the North American and Farallon Plates. Their study may not correspond to the Stonyford area, but certainly involves strike-slip offset of ophiolite fragments within the Central Belt of the Franciscan.

1.2.6 Intrusive-type model studies

Maxwell (1974) interpreted the Coast Range Ophiolite as an intrusive unit in the manner of Taliaferro (1943). He proposed the ophiolite as a diapiric intrusion and therefore concluded that the Franciscan/Great Valley contact was not a fault at all.

Figure 1.7. Normal-type model with exhumation of blueschist. Coast Range Fault is east-dipping accomodating eastward extension of Great Valley and Coast Range Ophiolite due to thickening from underplating, simplified from Ring and Brandon (1994) after Harms et al. (1992).

Figure 1.8. Hybrid-type model with normal faulting and tectonic wedging. Underplating and extension leads to a contractional regime along the same fault, simplified from Constenius et al. (2000) after Wakayashi and Unruh (1995).

1.2.7 Field-based studies

In the previous sections, six model-types were presented to explain how the Franciscan Complex and Coast Range Ophiolite are in contact and exposed at the surface using no field data as evidence. The following studies have collected structural data from the Coast Range Ophiolite and the Franciscan Complex. No structural data has previously been collected for the Stonyford area.

Coast Range Ophiolite studies

Ring and Brandon (1994) recorded structural data for 170 fault surfaces on seven roadside outcrops near the Beehive Flat area of the Yolla Bolly Mountains (Figure 1.9). They presented kinematic data for the Coast Range Fault and interpreted fault parallel contraction. They concluded that the Coast Range Fault is an out-of-sequence thrust fault which explains the metamorphic discontinuity across the fault and thus they proclaim that erosion and not extensional faulting is the dominant process in exhuming the Franciscan.

Huot and Maury (2002) collected structural data from 12 shear zones in the Round Mountain serpentinite mélange (Figure 1.9). Mean strike and dip of the shear zones was reported as 353°, 55°NE. The sense of slip for the shear zones was not indicated in the study but the mean strike and dip of the bedding surfaces was stated as 322°, 53°NE. From their conclusions, they suggested that the Round Mountain serpentinite mélange was formed by underthrusting beneath the upper Coast Range Ophiolite.

Dewhurst (2008) measured over 1,400 faults in three transects across the Coast Range Ophiolite near Paskenta. He found that faults traceable for ≥ 1 meter are similar in orientation to the Coast Range Fault, striking nearly north-south with moderate to steep dips and are evenly distributed across the

Figure 1.9. Map of previous field study locations discussed in text. Location of this study is within highlighted red box.

transects. He proposed a model with a four phase tectonic history: 1) Serpentinite mélangé generation; 2) Franciscan subduction initiation; 3) Subduction underplating; and 4) Exhumation.

Franciscan Complex studies

Copeland (1988) collected data from nine transects in the Eastern Belt of the Franciscan Complex north of San Francisco (Figure 1.9). The failure to find metamorphic discontinuities led him to conclude there was never kilometers of vertical offset along major faults as previously inferred by Suppe (1973) or Jayko and Blake (1989).

Chatawanich (2001) measured over 8,000 structures including foliations, fold hinges, bedding planes, fault planes, and veins in the Pacheco Pass area of the Diablo Range south of San Francisco (Figure 1.9). He found most folds post-date foliation formation, and believed folding was concurrent with normal faulting. He concluded the metamorphic foliation, and most veins were formed during horizontal extension.

Ring and Richter (2004) performed a strain analysis on sandstone samples collected from a shear zone at Del Puerto Canyon in the Diablo Range. They found no evidence for high strain or an increase in strain near the Coast Range Fault. They concluded that normal faulting was not the process that exhumed the Franciscan rocks and believed that unroofing was by erosion.

Perri (2005) measured foliations, fold hinges, fault planes, and other structures along 17 road cuts in the South Fork Mountain Schist of the coherent Eastern Belt of the Franciscan Complex about 50 km north of Stonyford (Figure 1.9). He made over 3,100 structural measurements mostly located near the Coast Range Fault. He found examples of normal faults cross cutting metamorphic foliations. He concluded that faulting and folding

occurred simultaneously as the Eastern Belt was exhumed through the brittle-ductile transition via normal faulting.

1.3 Summary

The contact between the Coast Range Ophiolite and the Franciscan Complex was first proposed as depositional, then intrusive, then as a fault with both major and modest offset, and slip ranging from reverse/thrust to normal, both high and low angle and even strike-slip. While the reported studies propose kinematics for the Franciscan Complex/Coast Range Fault/Coast Range Ophiolite-Great Valley Group, most have little or no corresponding direct field data from outcrops. The reverse-type models provide an explanation as to how the Franciscan Complex material reached high-pressure/low-temperature blueschist facies conditions (15-20 km), but the process of unroofing is problematic. Rocks are buried deeper and thus require 20+ km of erosion. Normal-type models can explain how Franciscan rocks can move toward the surface from great depths with little, if any, erosion.

The vast majority of work done in Northern California with respect to subduction has relied on models to explain the contacts between the different rocks. Field-based observations and kinematic field data are sparse. More field data are needed to constrain kinematics on the faulting that raised the Franciscan/ Coast Range Ophiolite /Great Valley Group. Four studies (Copeland, 1988; Chatawanich, 2001; Perri, 2005; and Dewhurst, 2008) were discussed in the previous section and all were graduate students from the University of Texas at Austin who have completed field-based research near the Coast Range Fault. This study presents field data collected near Stonyford, California within the Coast Range Ophiolite in attempt to further constrain the relationship between the Franciscan Complex and the Great Valley Group.

CHAPTER 2: FAULTING ANALYSIS

2.1 Introduction

The purpose of this study was to obtain fault orientation and slip data from the Coast Range Ophiolite in the Stonyford, California area to constrain the local kinematics and to evaluate previous large scale tectonic models. The Stonyford area was chosen because the Coast Range Fault deviates from its near north-south trend and forms a distinct bend or hook shape. Road cuts make the best exposures, and six transects could be made across the Coast Range Ophiolite utilizing U.S. Forest Service roads.

2.1.1 Field Location

The Coast Range Ophiolite near Stonyford, California is approximately 150 km north of San Francisco and is on the eastern edge of the Mendocino National Forest (Figure 1.3). The field study area is contained within the Stonyford and Elk Creek USGS 7.5 minute topographic quadrangle maps with a northern most heading of 39° 37' 30"N, 122° 36' 30"W and a southern most heading at 39° 18' 00"N, 122° 34' 00"W.

2.2 Lithologies

2.2.1 Mafic units

In the Stonyford field area, the only data collected on mafic rocks was along the eastern portion of the Fouts Springs Transect (Figure 2.1). In this locality, the mafics were well exposed in four separate, but extremely weathered, outcrops. Most of the faults were easily exposed by excavation. All four had blocks of pillow basalt (Figure 2.2). At outcrops B and C, a chert called the Stonyford Jasper (Figure 2.3) outcropped as small (< 1 m) nodules.

Figure 2.1. Outcrop map of the Fouts Springs Transect.

Figure 2.2. (a) Example of a mafic outcrop with pillow basalts.
 (b) Fault and pillows outlined (Fout Springs Transect, Outcrop B).

In a few localities, small amounts of copper staining (Figure 2.3) was found in association with chert nodules.

2.2.2 Serpentinities

Serpentinities underlies most of the area mapped as Coast Range Ophiolite and more than 95% of the fault data collected were from this rock type. Depending on the locality, the color and textures varied. The southernmost transects of the field area are mostly massive blocks, while the northernmost transects are mostly foliated serpentinite. Along the Goat Mountain Road (Figure 2.4), the serpentinite is mostly teal-green and bluish gray with some white, mostly massive blocks (Figure 2.5 and 2.6) with roughly 70% weathered and 30% fresh exposed surfaces. Along the Black Diamond Transect (Figure 2.7), the outcrops are mostly foliated (Figure 2.8) and usually a dark green to olive green color with few fresh surfaces. Most surfaces are weathered. Foliation surfaces are spaced millimeters to one or two centimeters apart. Foliated serpentinite is far more prone to erosion and thus poorly exposed, compared to massive blocky serpentinite. The other transects contain a mixture of foliated serpentinites with massive blocks (Figure 2.9). Foliated serpentinite zones can be many meters in thickness.

2.3 Field Methods

Fault data were collected from nine outcrops along Goat Mountain Road with 4 km of exposure, six outcrops along Fouts Springs Road with 1.5 km of exposure, two along 18N03/18N06 National Forest Service trails (Mill Creek Transect, Figure 2.10) with 1.75 km of road exposure, one along 18N03/18N04 National Forest Service trails (North Fork Stony Creek Transect, Figure 2.11) with 0.5 km of exposure, two along 18N02 National Forest Service trail (Black Diamond Transect) with 3 km of exposure, and one

Figure 2.10. Outcrop map of the Mill Creek Transect.

Figure 2.11. Outcrop map of the North Fork Stony Creek Transect.

along County Road 309 (Figure 2.12) with approximately 30 meters exposed. Fault data were collected from 21 outcrops totaling 10.7 km length of transect.

Exposures were best in the southern portion of the field area because these outcrops were mostly massive serpentinite. The roadcuts along the northern transects particularly in areas between the acute and obtuse bends were typically poor and highly weathered. These outcrops were mostly foliated serpentinites.

All faults traceable more than 10 centimeters and less than three meters above the base of the exposed roadcut were recorded. Information collected include lithology, fault orientation, fault plane exposure length, slickenline orientation, and sense of shear. Fault planes that were measured were divided into three groups: fault planes without slickenlines, fault planes with slickenlines, and fault planes with slickenlines and steps indicating shear sense.

2.4 Fault Analysis Methods

Stereonet were used to plot fault plane orientation and slickenline data. Fault orientation data were recorded using azimuthal right-hand rule with the dip direction 90° clockwise from strike. Trend and plunge was used to record lineation data. For faults with lineations, rakes were calculated with OSXGeoCalc v.3.4 by Nestor Cardozo. Each of these faults was classified as strike-slip (rake $\leq 30^\circ$), oblique-slip (rake $> 30^\circ$ and $< 60^\circ$), or dip-slip (rake $\geq 60^\circ$) based on the above mentioned criteria. Poles to fault planes and lineation data for Figures 2.50-2.61 were plotted using Stereonet 7.2.1 – 2011 for Windows by Richard Allmendinger. Contoured poles to fault planes and lineation data for Figures 2.16-2.49 and 2.62-2.70 were plotted using OSXStereonet 2011 (based on Stereonet by Richard Allmendinger) for Mac

Figure 2.12. Outcrop map of the County Road 309 Transect.

by Nestor Cardozo and Richard Allmendinger.

The fault and lineation data were contoured using Kamb's (1959) method. This is a statistical method in which the frequency of data points within a certain area is compared against a uniform distribution. The Kamb algorithm is used to contour the data at two standard deviations away from the uniform distribution. If statistically significant, the stereonet will show a strong preferred orientation (point maximum) as indicated by dark shaded areas.

2.5 Coast Range Fault Orientation

One direct measurement of the Coast Range Fault orientation was collected along Goat Mountain Road with a heading of $39^{\circ} 17' 12''\text{N}$, $122^{\circ} 34' 45''\text{W}$ (Figure 2.13). The orientation of the Coast Range Fault at this locality is $\text{N}18^{\circ}\text{E}$, 70°SE (Figure 2.14, #1). At this location and seven other sites, the orientation of the Coast Range Fault was determined using the three-point problem method (Figure 2.15). Using three points of known location and elevation that mark the outcrop of a plane can always be used to calculate strike and true dip of that plane. Aerial photography was used to determine the limits to serpentinite and Franciscan exposures. This was possible due to the scarcity of plant growing nutrients supplied to the soils by the serpentinized rocks below. Topographic maps were used to attain elevations for creek beds and local high spots along the Coast Range Fault. The calculated orientation for the Goat Mountain Road along Little Stony Creek was nearly identical to the direct measurement with a northeast strike dipping 70°SE . Hyphus Creek intersects the Coast Range Fault with a heading of $39^{\circ} 15' 52''\text{N}$, $122^{\circ} 34' 82''\text{W}$ and the calculated orientation is $\text{N}35^{\circ}\text{W}$, 77°NE (Figure 2.14, #2). Salt Creek intersects the Coast Range Fault with a heading

Figure 2.13. (a) Coast Range Fault contact between Franciscan slate and foliated serpentinite. Orientation of Coast Range Fault at this location is 018° , 70° SE. (b) Coast Range Fault is highlighted and traceable for approximately 2.5 meters (Goat Mountain Road Transect, Outcrop A and B).

Figure 2.14. (a) Map of Stonyford, California field area with location of Coast Range Fault orientations via direct measurement and three point problem. Determination of Coast Range Fault orientations is discussed in the text (see 2.5 Coast Range Fault Data). (b) Equal-area stereonet plot of poles to planes of the Coast Range Fault, determined by three-point-problem calculation.

Figure 2.15. Composite of aerial photography used for three-point-problem analysis of Coast Range Fault orientation. Star indicates creek bed where three-point-problem calculation was made for Coast Range Fault orientation. White circles flanking star indicate higher elevations along Coast Range Fault (shown as feet above creek bed elevation).

of $39^{\circ} 20' 80''\text{N}$, $122^{\circ} 36' 52''\text{W}$ and the calculated orientation is $\text{N}60^{\circ}\text{W}$, 52° NE (Figure 2.14, #3). Stony Creek intersects the Coast Range Fault with a heading of $39^{\circ} 22' 07''\text{N}$, $122^{\circ} 38' 28''\text{W}$ and the calculated orientation of the fault is $\text{N}24^{\circ}\text{W}$, 83° SW (Figure 2.14, #4). South Fork Stony Creek intersects the Coast Range Fault with a heading of $39^{\circ} 15' 52''\text{N}$, $122^{\circ} 34' 82''\text{W}$ and the calculated orientation is $\text{N}10^{\circ}\text{W}$, 53° NE (Figure 2.14, #5). Middle Fork Stony Creek intersects the Coast Range Fault with a heading of $39^{\circ} 15' 52''\text{N}$, $122^{\circ} 34' 82''\text{W}$ and the calculated orientation of $\text{N}04^{\circ}\text{E}$, 73° W (Figure 2.14, #6). North Fork Stony Creek intersects the Coast Range Fault with a heading of $39^{\circ} 15' 52''\text{N}$, $122^{\circ} 34' 82''\text{W}$ and the calculated orientation is $\text{N}46^{\circ}\text{E}$, 70° NW (Figure 2.14 #7). Dry Creek intersects the Coast Range Fault with a heading of $39^{\circ} 15' 52''\text{N}$, $122^{\circ} 34' 82''\text{W}$ and the calculated orientation is $\text{N}87^{\circ}\text{W}$, 42° NE (Figure 2.14, #8). In the following section (2.6 Fault Data), all fault data is used to determine how the orientation of minor faults within the Coast Range Ophiolite compare to the orientation of the Coast Range Fault.

2.6 Fault Data

In the following sections, data in the form of maps and stereonet will be discussed for each transect by the number of fault planes measured, the number of those faults with slickenlines, and the number of slickenlines containing steps indicating the sense of slip for that fault (Figure 2.16). Field data are also characterized by number and type of fault along each transect. In the following sections, the magnitude of the dip of a plane or the plunge of a lineation will be referred to by the terms shallow ($< 30^{\circ}$), moderate (30° - 60°), and steep ($> 60^{\circ}$).

Figure 2.16. Slickensite steps showing normal movement along a near vertical face of massive serpentinite (Goat Mountain Road Transect, Outcrop G). Pencil is pointed in the direction of slip motion along the fault plane.

2.6.1 Goat Mountain Road Transect Data

Along the Goat Mountain Road Transect, 610 fault planes were measured, 211 of these faults had slickenlines, and 164 contained steps. Of the faults that contain steps, 62 (38%) are normal faults, 15 (9%) are reverse faults, 4 (2%) are left-lateral faults, 10 (6%) are right-lateral faults, 16 (10%) are normal left-lateral faults, 33 (20%) are normal right-lateral faults, 15 (9%) are reverse left-lateral faults, and 9 (5%) are reverse right-lateral faults (Table 2.1). Of the faults that have slickenline data, 47 did not have steps and therefore the specific type of fault offset could not be determined in the field.

There are 89 dip-slip faults (Figure 2.17). The normal faults have a strong preferred orientation. Most normal faults strike northeast to southwest and are steeply dipping to the southeast. Normal fault slickenline data (Figure 2.18) have a strong preferred orientation trending mostly southeast with a near vertical plunge.

There are 100 oblique-slip faults (Figure 2.19). Most are normal right-lateral faults, which strike northwest to southeast and steeply dip to the southwest. The others are normal left-lateral and reverse left-lateral faults both with a strike northwest to southeast, dipping steeply to the southwest. For normal left-lateral, normal right-lateral, and oblique-slip faults there is a strong preferred orientation of slickenlines (Figure 2.20) trending southeast with a moderate plunge.

There are 22 strike-slip faults (Figure 2.21). There is no preferred orientation for strike-slip faults or slickenlines (Figure 2.22) for strike-slip faults.

Along the Goat Mountain Road Transect, 111 of 164 (68%) faults display normal-type displacement, 39 of 164 (24%) display reverse-type

Figure 2.17. Equal-area stereonet plots of poles to all Goat Mountain Road (a) dip-slip faults, (b) normal faults, and (c) reverse faults. The contour interval for this and all the following stereonet is two standard deviations.

Figure 2.19. Equal-area stereonet plots of poles to all Goat Mountain Road (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults, (d) reverse left-lateral faults, and (e) reverse right-lateral faults.

Figure 2.20. Equal-area stereonet plots of slickenlines for all Goat Mountain Road (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults, (d) reverse left-lateral faults, and (e) reverse right-lateral faults.

Figure 2.21. Equal-area stereonet plots for poles to all Goat Mountain Road (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

Figure 2.22. Equal-area stereonet plots of slickenlines for all Goat Mountain Road (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

displacement, 35 of 164 (21%) display left-lateral-type displacement, and 53 of 164 (32%) display right-lateral-type displacement. There were 610 fault planes measured along 4 kilometers of outcrop with an average spacing of about one fault per seven meters. Orientations of normal faults along the Goat Mountain Road Transect closely mimic the local Coast Range Fault data. The normal faults parallel the Coast Range Fault both striking northeast/southwest dipping steeply to the southeast.

All faults along Goat Mountain Road

Faults are not distributed evenly across the Goat Mountain Road outcrops (Figure 2.23). A total of 610 faults were measured across the transect. Outcrop F (0.4 km in length) contains the most faults [n = 271 of 610, (44%)] and is centrally located along the transect. Outcrop G (0.3 km in length) contains the second most number of faults [n = 90, (15%)] and also is in a central location. Outcrop C contains the third most number of faults [n = 84, (14%)] and is the closest outcrop outside of Outcrop B to the Coast Range Fault. Outcrop C (40 meters in length), the smallest outcrop in length, contains the most faults per unit length. With exception to Outcrop B and Outcrop D, all outcrops are exceptional. There is no strong preferred orientation of faults along the outcrops. There is a weak preferred orientation along Outcrops B, C, F, H, and J with strike northwest to southeast dipping moderately to steeply southwest.

Slickenlines for all faults along Goat Mountain Road Transect

Slickenlines for all faults are not evenly distributed across the Goat Mountain Road outcrops (Figure 2.24). A total of 211 slickenlines for all faults were measured across the transect. Outcrop F contains the most slickenlines [n = 87 of 211, (41%)] and is centrally located along the transect. Outcrop G contains the second most number of slickenlines to faults [n = 40, (19%)] and

Figure 2.23. Equal area stereonet plots for poles to all fault planes along Goat Mountain Road Transect. See Figure 2.1 for the explanation of symbols.

Figure 2.24. Equal area stereonet plots of slickenlines for all faults along Goat Mountain Road Transect. See Figure 2.1 for the explanation of symbols.

also is in a central location. Outcrop C contains the third most number of faults with slickenlines [$n = 26$, (12%)]. There is a moderate to strong preferred orientation of slickenlines along Outcrops F, G, H, and J. The trend is southeast with a moderate to steep plunge.

2.6.2 Fouts Springs Transect Data

Along the Fouts Springs Transect, 238 fault planes were measured, 94 of these faults have slickenlines, and 69 contain steps. Of the faults that contain steps, 28 (41%) are normal faults, 11 (16%) are reverse faults, 3 (4%) are left-lateral faults, 5 (7%) are right-lateral faults, 4 (6%) are normal left-lateral faults, 11 (16%) are normal right-lateral faults, 5 (7%) are reverse left-lateral faults, and 2 (3%) are reverse right-lateral faults (Table 2.1). Of the faults that have slickenline data, 25 did not have steps and therefore the specific type of fault could not be determined.

There are 42 dip-slip faults (Figure 2.25). There are two weak preferred orientations for normal faults, one with a strike northeast to southwest and moderately dipping to the southeast, and the other with a strike northeast to southwest dipping moderately to the northwest. Normal fault slickenline data (Figure 2.26) has a strong preferred orientation trending mostly east with a steep plunge. Reverse fault slickenline data (Figure 2.26b) has a preferred orientation trending north to east with a nearly vertical plunge.

There are 39 oblique-slip faults (Figure 2.27). There is a slight preferred orientation of all oblique-slip faults with a strike northwest to southeast dipping moderately to the southwest. There is no preferred orientation of slickenlines (Figure 2.28) for any oblique-slip fault.

Figure 2.25. Equal-area stereonet plots of poles to all Fouts Springs (a) dip-slip faults, (b) normal faults, and (c) reverse faults.

Figure 2.27. Equal-area stereonet plots of poles to all Fouts Springs (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults, (d) reverse left-lateral faults, and (e) reverse right-lateral faults.

Figure 2.28. Equal-area stereonet plots of slickenlines for all Fouts Springs (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults, (d) reverse left-lateral faults, and (e) reverse right-lateral faults.

There are 12 strike-slip faults (Figure 2.29). There is no preferred orientation for strike-slip faults or slickenlines (Figure 2.30) for strike-slip faults.

Along the Fouts Springs Transect, 43 of 69 (62%) faults display normal-type displacement, 18 of 69 (26%) display reverse-type displacement, 12 of 69 (17%) display left-lateral-type displacement, and 18 of 69 (26%) display right-lateral-type displacement. There were 238 fault planes measured along 1.5 kilometers of outcrop, with exposures averaging one fault per six meters. Preferred orientations of faults along this transect do not parallel the local Coast Range Fault data which is striking northwest/southeast and dipping 83° to the southwest.

All faults along Fouts Springs Transect

Faults are not distributed evenly across the Fouts Springs outcrops (Figure 2.31). A total of 238 faults were measured along the transect. Outcrops A, B, C, and D are all primarily mafic and contain 45 of 238 faults (19%). The other 193 faults (81%) are located in serpentinite outcrops. Outcrop E contains the most faults [n = 108 of 238, (45%)] and is the easternmost and smallest serpentinite outcrop containing the most faults per area. Outcrop F is centrally located and contains the second most number of faults [n = 55 of 238, (23%)]. Outcrop G contains the third most number of faults [n = 30, (13%)] and is the closest outcrop to the Coast Range Fault forming a contact with the Franciscan. The three serpentinitized Outcrops E, F, and G are fair to good exposures, and are mostly massive with some serpentinite mélange. The mafic Outcrops A, B, C, and D are extremely weathered with poor to fair exposures. There is no strong preferred orientation of faults among the mafic outcrops. There is no preferred orientation for Outcrop E, but there are three distinct clusters of orientations

Figure 2.29. Equal-area stereonet plots for poles to all Fouts Springs (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

Figure 2.30. Equal-area stereonet plots of slickenlines for all Fouts Springs (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

Figure 2.31. Equal area stereonet plots for poles to all fault planes along Fouts Springs Transect. See Figure 2.1 for the explanation of symbols.

for faults at this outcrop. One cluster strikes northeast/southwest dipping moderately to the southeast. The second cluster strikes northwest/southeast dipping moderately to the southwest and lastly, the third cluster strikes north/south dipping moderately to the west. Outcrop G has a slight preferred orientation with faults striking north-northeast/south-southwest dipping moderately to the east-southeast. There is a good preferred orientation for Outcrop F with faults striking northwest/southeast and dipping moderately to the southwest.

Slickenlines for all faults along Fouts Springs Transect

Slickenlines for all faults are not evenly distributed with respect to the serpentinized outcrops (Figure 2.32). A total of 94 slickenlines for all faults were measured along the transect. Outcrop E contains the most slickenlines [n = 39 of 94, (41%)]. Outcrop F contains second most number of slickenlines to faults [n = 22, (23%)]. Outcrop G contains the third most number of slickenlines to faults [n = 13, (14%)]. There is a weak preferred orientation of slickenlines to faults along Outcrops F. The trend is south-southeast with a shallow plunge.

2.6.3 Mill Creek Transect Data

Along the Mill Creek Transect, 66 fault planes were measured, 29 of these faults have slickenlines, and 26 of which contain steps. Of the faults that contained steps, 8 (31%) are normal faults, 3 (11%) are reverse faults, 3 (11%) are left-lateral faults, 3 (11%) are right-lateral faults, 2 (8%) are normal left-lateral faults, 4 (15%) are normal right-lateral faults, 1 (4%) are reverse left-lateral faults, and 2 (8%) are reverse right-lateral faults (Table 2.1). Of the faults that have slickenline data, three did not have steps. Therefore, the specific type of fault could not be determined in the field.

Figure 2.32. Equal area stereonet plots of slickenlines for all faults along Fouts Springs Transect. See Figure 2.1 for the explanation of symbols.

There are 11 dip-slip faults (Figure 2.33). There is no preferred orientation for dip-slip faults. There is, however, a moderately preferred orientation of slickenlines (Figure 2.34) for all dip-slip faults trending west/northwest to south/southeast with a near vertical plunge.

There are 12 oblique-slip faults (Figure 2.35). There is no preferred orientation of oblique-slip faults or slickenlines (Figure 2.36) for oblique-slip faults.

There are six strike-slip faults (Figure 2.37). There is no preferred orientation for strike-slip faults or slickenlines (Figure 2.38) for strike-slip faults.

Along the Mill Creek Transect, 14 of 26 (54%) faults display normal-type displacement, 6 of 26 (23%) display reverse-type displacement, 6 of 26 (23%) display left-lateral-type displacement, and 9 of 26 (35%) display right-lateral-type displacement. There were 66 fault planes measured along 1.75 kilometers of outcrop, with exposures averaging one fault per 27 meters. Preferred orientations of faults along this transect do not parallel the local Coast Range Fault data which strikes nearly north-south dipping 53° to the northeast.

All faults along Mill Creek Transect

Faults are not evenly distributed between the two Mill Creek outcrops (Figure 2.39). A total of 66 faults were measured along the transect, with most faults found at Outcrop B [57 of 66, (86%)]. Outcrop B is located to the northwest of trail 18N03 along the Middle Fork Stony Creek (Figure 2.39). There is a weak to moderate preferred orientation of faults along Outcrop B with a strike north/south dipping steeply to the west. Outcrop A is near the

Coast Range Fault, which is not exposed, making the faults exact location within a 15 meter section.

Slickenlines for all faults along Mill Creek Transect

Slickenlines for all faults are not evenly distributed amongst the two outcrops contain faults (Figure 2.40). A total of 29 slickenlines were measured with Outcrop B containing the most fault slickenlines [$n = 26$ of 29, (90%)]. There is no preferred orientation of slickenlines to faults for either outcrop along the Mill Creek Transect.

2.6.4 North Fork Stony Creek Transect Data

Along the North Fork Stony Creek Transect, 27 fault planes were measured, 13 of these faults have slickenlines, and 11 of which contain steps. Of the faults that contain steps, 5 (45%) are normal faults, 1 (9%) are reverse faults, there are no left-lateral faults, 3 (27%) are right-lateral faults, 1 (9%) are normal left-lateral faults, 1 (9%) are normal right-lateral faults, there are no reverse left-lateral or reverse right-lateral faults (Table 2.1). Of the faults that have slickenline data two did not have steps and therefore the specific type of fault could not be determined.

There are six dip-slip faults (Figure 2.41). There is a weak preferred orientation for dip-slip faults striking northeast to southwest and moderately to steeply dipping to the southeast. There is a weak preferred orientation of slickenlines (Figure 2.42) for normal faults trending southeast with a moderate plunge. Not enough data was collected for reverse faults to have statistical significance.

There are four oblique-slip faults (Figure 2.43). Not enough data was collected for oblique-slip fault slickenlines (Figure 2.44) to have statistical significance.

Figure 2.40. Equal area stereonet plots of slickenlines for all faults along Mill Creek Transect. See Figure 2.1 for the explanation of symbols.

Figure 2.42. Equal-area stereonet plots of slickenlines for all North Fork Stony Creek (a) dip-slip faults, (b) normal faults, and (c) reverse faults.

Figure 2.43. Equal-area stereonet plots of poles to all North Fork Stony Creek (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults. No faults were measured that have reverse left-lateral or reverse right-lateral sense of slip.

Figure 2.44. Equal-area stereonet plots of slickenlines for all North Fork Stony Creek (a) oblique-slip faults, (b) normal left-lateral faults, and (c) normal right-lateral faults. No faults were measured that have reverse left-lateral and reverse right-lateral sense of slip.

There are three strike-slip faults (Figure 2.45). Not enough data was collected for any strike-slip fault slickenlines (Figure 2.46) to have statistical significance.

Along the North Fork Stony Creek Transect, 7 of 11 (64%) faults display normal-type displacement, 1 of 11 (9%) display reverse-type displacement, 1 of 11 (9%) display left-lateral-type displacement, and 4 of 11 (36%) display right-lateral-type displacement. There were 27 fault planes measured along 0.5 kilometers of outcrop, averaging about one fault per 19 meters. Preferred orientations of faults along this transect do parallel the local Coast Range Fault data which strikes northeast/southwest and dips 70° to the northwest.

All faults along North Fork Stony Creek Transect

A total of 27 faults were measured along the North Fork Stony Creek Transect (Figure 2.47). Outcrop A is a poorly to fairly exposed outcrop, but the best along the transect and is where all the fault data was attained. There is a moderate preferred orientation of faults along Outcrop A with a strike east-northeast/west-southwest dipping steeply to the north-northwest.

Slickenlines for all faults along North Fork Stony Creek Transect

A total of 13 slickenlines to faults were measured at Outcrop A (Figure 2.48). There is no preferred orientation of slickenlines to faults. However, the majority of the slickenlines trend to the southeast and have a moderate to steep plunge.

2.6.5 Black Diamond Transect Data

Along the Black Diamond Transect, 146 fault planes were measured, 58 of these faults have slickenlines, and 42 contain steps. Of the faults that

Figure 2.45. Equal-area stereonet plots for poles to all North Fork Stony Creek right-lateral faults. No left-lateral faults were measured.

Figure 2.46. Equal-area stereonet plots of slickenlines for all North Fork Stony Creek right-lateral faults. No left-lateral faults were measured.

Figure 2.47. Equal area stereonet plots for poles to all fault planes along North Fork Stony Creek Transect. See Figure 2.1 for the explanation of symbols.

Figure 2.48. Equal area stereonet plots of slickenlines for all faults along North Fork Stony Creek Transect. See Figure 2.1 for the explanation of symbols.

contain steps, 11 (26%) are normal faults, 7 (17%) are reverse faults, 1 (2%) is a left-lateral fault, 3 (7%) are right-lateral faults, 4 (10%) are normal left-lateral faults, 14 (33%) are normal right-lateral faults, 2 (5%) are reverse left-lateral faults, and there are no reverse right-lateral faults (Table 2.1). Of the faults that have slickenline data 16 did not have steps and therefore, the specific type of fault offset could not be determined.

There are 22 dip-slip faults (Figure 2.49). There is no preferred orientation for any dip-slip faults. There is, however, a strong preferred orientation of slickenlines (Figure 2.50) for normal faults trending west to east with a steep plunge.

There are 32 oblique-slip faults (Figure 2.51). There is a weak preferred orientation of normal right-lateral faults, which strike northwest to southeast and dip moderately to the southwest. There is no preferred orientation of slickenlines (Figure 2.52) for oblique-slip faults.

There are four strike-slip faults (Figure 2.53). Not enough data was collected for strike-slip fault slickenlines (Figure 2.54) to have statistical significance.

Along the Black Diamond Transect, 29 of 42 (69%) faults display normal-type displacement, 9 of 42 (21%) display reverse-type displacement, 7 of 42 (17%) display left-lateral-type displacement, and 17 of 42 (40%) display right-lateral-type displacement. There were 146 fault planes measured along 3 kilometers of outcrop, averaging about one fault per 21 meters. Preferred orientations of faults along this transect do not parallel the local Coast Range Fault data which strikes east/west dipping 42° to the north.

Figure 2.49. Equal-area stereonet plots of poles to all Black Diamond (a) dip-slip faults, (b) normal faults, and (c) reverse faults.

Figure 2.51. Equal-area stereonet plots of poles to all Black Diamond (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults, and (d) reverse left-lateral faults. No reverse right-lateral faults were measured.

Figure 2.52. Equal-area stereonet plots of slickenlines for all Black Diamond (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults, and (d) reverse left-lateral faults. No reverse right-lateral faults were measured.

Figure 2.53. Equal-area stereonet plots for poles to all Black Diamond (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

Figure 2.54. Equal-area stereonet plots of slickenlines for all Black Diamond (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

All faults along Black Diamond Transect

Faults are not distributed evenly between the two Black Diamond outcrops. A total of 146 faults were measured along the transect (Figure 2.55) with most faults found at Outcrop A [103 of 146, (71%)]. Outcrop A has the best exposures along this transect and is near the Coast Range Fault, which is not exposed, making the faults exact location within a 10 meter section. There is no preferred orientation of faults at Outcrop A. However, most faults at Outcrop B strike northwest/southeast and dip shallow to steep to the southwest.

Slickenlines for all faults along Black Diamond Transect

Slickenlines for all faults are not evenly distributed amongst the two outcrops with fault measurements (Figure 2.56). A total of 58 slickenlines for all faults were measured across the transect. Outcrop A contains the most slickenlines [n = 41 of 58, (71%)]. There is no obvious preferred orientation of slickenlines on faults for either outcrop along the Black Diamond Transect.

2.6.6 County Road 309 Transect Data

Along the County Road 309 Transect, 21 fault planes were measured, nine of these faults have slickenlines, and seven contain steps. Of the faults that contain steps, three (43%) are normal faults, there are no reverse faults, there are no left-lateral faults or right-lateral faults, one (14%) are normal left-lateral faults, two (29%) are normal right-lateral faults, there are no reverse left-lateral faults, and one (14%) are reverse right-lateral faults (Table 2.1). Of the faults that have slickenline data two did not have steps and therefore the specific type of fault could not be determined in the field.

Figure 2.55. Equal area stereonet plots for poles to all fault planes along Black Diamond Transect. See Figure 2.1 for the explanation of symbols.

Figure 2.56. Equal area stereonet plots of slickenlines for all faults along Black Diamond Transect. See Figure 2.1 for the explanation of symbols.

There are three dip-slip faults (Figure 2.57). There is not enough data collected for normal fault slickenlines (Figure 2.58) to have statistical significance.

There are six oblique-slip faults (Figure 2.59). Not enough data was collected for oblique-slip fault slickenlines (Figure 2.60) to have statistical significance.

Along the County Road 309 Transect, 6 of 7 (86%) faults display normal-type displacement, 1 of 7 (14%) display reverse-type displacement, 1 of 7 (14%) display left-lateral-type displacement, and 3 of 7 (43%) display right-lateral-type displacement. There were 21 fault planes measured along 30 meters of outcrop, averaging about one fault per 1.5 meters. Coast Range Fault data was not calculated via the three-point problem method near this transect. Additionally, not enough data was collected from this transect to make statistical comparisons.

All faults along County Road 309 Transect

A total of 21 faults were measured along the County Road 309 Transect (Figure 2.61). Outcrop A is a good exposure, but small. Beyond Outcrop A to the west outcrops are extremely poor and there is no surface evidence of the Coast Range Fault. There is a preferred orientation of faults along Outcrop A with a strike northeast to southwest dipping steeply to the northwest.

Slickenlines for all faults along County Road 309 Transect

A total of nine slickenlines for all faults were measured across the transect (Figure 2.62). There is no preferred orientation of slickenlines to faults for the County Road 309 Transect.

Figure 2.57. Equal-area stereonet plots of County Road 309 transect poles to all normal faults.

2.6.7 Transect Comparison

Distribution of the different types of faults is scattered as all fault types occurred in most transects. Of the faults measured, where type of fault was determined, the North Fork Stony Creek Transect has the highest percentage of strike-slip faults (27%). The Mill Creek Transect has 23% strike-slip faults. All the other transects contained approximately 10% strike-slip faults with the exception of the County Road 309 Transect where no strike-slip faults were found. The Mill Creek, North Fork Stony Creek, and Black Diamond Transects contains mostly foliated serpentinite outcrops.

The most coherent and massive serpentinite outcrops were located in the southern portion of the field area including the Goat Mountain Road and Fouts Springs Transects. Fouts Springs Transect contained the highest percentage of dip-slip faults. Of the faults with lineations and steps that were measured along this transect, 39 of 69 (57%) are dip-slip faults. Along Goat Mountain Road 164 faults with lineations and steps were measured, 77 (47%) are dip-slip faults. 43% of the faults with lineations and steps for the County Road 309 Transect are dip-slip, 42% at Mill Creek are dip-slip, and 43% at Black Diamond are dip-slip.

There is a strong preferred orientation for all faults along the Goat Mountain Road Transect striking northwest to southeast dipping steeply to the southwest (Figure 2.63a). Fouts Springs Transect shows a strong preferred orientation striking northeast to southwest dipping moderately to steeply southeast (Figure 2.63b). Mill Creek has a strong preferred orientation with a strike north to south dipping moderately to steeply west (Figure 2.63c). Poles to all North Fork Stony Creek (Figure 2.63d) faults show a strong preferred orientation with a strike east-northeast to west-southwest dipping steeply to the north-northwest. There are two strong preferred orientations for faults

Figure 2.63. Equal-area stereonet plots of poles to all faults along (a) Goat Mountain Road, (b) Fouts Springs, (c) Mill Creek, (d) North Fork Stony Creek, (e) Black Diamond, and (f) County Road 309.

along the Black Diamond Transect (Figure 2.63e). The first has a strike northwest to southeast dipping moderately to steeply southwest. The second has a northeast to southwest strike with a moderate dip northwest. County Road 309 has a strong preferred orientation (Figure 2.63f) for all faults with a northeast to southwest strike, dipping steeply to the northwest. In all instances but one (Fouts Springs), preferred dip orientations are westerly.

Slickenlines for all faults along Goat Mountain Road Transect shows a strong preferred orientation, trending southeast with a shallow to steep plunge (Figure 2.64a). Black Diamond Transect has a moderate preferred orientation of slickenlines for all faults trending east with a moderate plunge (Figure 2.64e). Fouts Springs, Mill Creek, North Fork Stony Creek, and County Road 309 Transects do not have a clear preferred orientation of slickenlines for all faults (Figure 2.64b, c, d, and f).

2.6.8 All Transects

In the field, 1,108 total faults were measured, 414 of these faults have slickenlines, and 319 contain steps. Of the faults that contain steps, 154 (48%) are dip-slip faults, 130 (41%) are oblique-slip faults, and 35 (11%) are strike slip faults (Table 2.1). 95 faults that have slickenlines did not have steps and therefore the specific type of fault could not be determined. There are three point maxima to all faults for all transects (Figure 2.65a) with a strike northwest to southeast dipping steeply to the southwest, a strike northeast to southwest dipping moderately to the northwest, and a strike northeast to southwest dipping steeply to the southeast. The slickenlines for all faults to all transects (Figure 2.65b) shows a strong preferred orientation trending southeast with a shallow to steep plunge. Poles to all faults with lineations and steps (Figure 2.65c) have a strong preferred orientation with a strike northeast to southwest dipping steeply to the southeast. There is also a

Table 2.1. (a) Fault data separated by number of fault planes, lineations, and lineations with steps with respect to each transect. (b) Fault data separated by type of fault with respect to each transect. Totals for both charts are indicated in a column separated by a bold line.

Figure 2.65. Equal-area stereonet plots for all six transects of (a) poles to all faults, (b) slickenlines for all faults, (c) poles to all faults with lineations and steps, and (d) slickenlines for all faults with lineations and steps.

moderately preferred orientation for poles to all faults with lineations and steps (Figure 2.65c) with a strike of northwest to southeast dipping moderately to steeply southwest.

Nearly half the faults (48%) measured with slickenlines and steps are dip-slip faults. Of the 173 dip-slip faults measured, 154 had steps, 117 (76%) are normal faults, and 37 (24%) are reverse faults. Normal faults account for 37% of all the faults with lineations and steps (319) measured across all transects. There is a strong preferred orientation for all normal faults striking northeast to southwest dipping steeply to the southeast (Figure 2.66b). There is a weak preferred orientation for all reverse faults striking northwest to southeast dipping steeply to the northeast (Figure 2.66c). There are strong preferred orientations of slickenlines for all normal and reverse faults (Figure 2.67). Both trend to the east with a steep plunge.

There are 65 (50%) normal right-lateral faults, 28 (21%) normal left-lateral faults, 23 (18%) reverse left-lateral faults, and 14 (11%) reverse right-lateral faults. There is a strong preferred orientation of all normal right-lateral faults ($n = 65$) with a strike northwest to southeast dipping steeply to the southwest (Figure 2.68c). Normal left-lateral faults and reverse left-lateral faults have a moderate preferred orientation striking northwest to southeast dipping steeply to moderately southwest (Figure 2.68b & d). There is a strong preferred orientation of slickenlines for all normal right-lateral and normal left-lateral faults (Figure 2.69). Both trend to the south-southeast with a moderate to steep plunge.

There are 47 strike-slip faults measured, 24 (69%) are right-lateral strike-slip faults, and only 11 (31%) are left-lateral faults. There are no preferred orientations for all right-lateral or left-lateral strike-slip faults (Figure 2.70). There are two moderate preferred orientations of slickenlines for all

Figure 2.66. Equal-area stereonet plots for all six transects of poles to (a) dip-slip faults, (b) normal faults, and (c) reverse faults.

Figure 2.69. Equal-area stereonet plots for all six transect of slickenlines for (a) oblique-slip faults, (b) normal left-lateral faults, (c) normal right-lateral faults, (d) reverse left-lateral faults, and (e) reverse right-lateral faults.

Figure 2.70. Equal-area stereonet plots for all six transects of poles to (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

Figure 2.71. Equal-area stereonet plots for all six transects of slickenlines for (a) strike-slip faults, (b) left-lateral faults, and (c) right-lateral faults.

strike-slip faults (Figure 2.71), the first trends north with a shallow plunge and the second trends south with a shallow plunge.

Across all transects 210 of 319 (66%) faults display normal-type displacement, 74 of 319 (23%) display reverse-type displacement, 62 of 319 (19%) display left-lateral-type displacement, and 103 of 319 (32%) display right-lateral-type displacement. There were 1,108 fault planes measured across all six transects along 10.8 kilometers of total outcrop averaging about one fault per 10 meters.

2.7 Summary

Orientations of 1,108 fault planes, 414 with slickenlines, and 319 with steps were measured at 22 roadcuts along six transects within the Coast Range Ophiolite in the Stonyford, California area. The major observations/results are:

1. Transects in the southern portion of the field area (Goat Mountain Road and Fouts Springs) are typically massive outcrops of serpentinite. The transects where data were collected from the northern portions (Black Diamond, North Fork Stony Creek, and Mill Creek) are typically poorly exposed foliated serpentinites.
2. Eight orientations were attained for the Coast Range Fault (Figure 2.14). The strikes range from northeast to southwest and from northwest to southeast dipping 53° to 83° to the east and west. There was only one direct measurement of the Coast Range Fault (N18°E, 70° SE) along the Goat Mountain Road Transect (Figure 2.14) striking northeast southwest with a steep dip southeast.
3. The preferred orientation for all normal faults (Figure 2.66b) closely mimics that of the direct measurement of the Coast Range Fault striking northeast to southwest dipping steeply to the southeast.

4. The percentages of faults with full kinematics normal, reverse, left-lateral, and right-lateral faults along each transect were consistent. About two-thirds having normal-type displacement, 25% having reverse displacement, and the remainder (~9%) are strike-slip. About one-fifth have left-lateral oblique or strike-slip displacement, and one-third have right-lateral oblique or strike-slip displacement (overlap in style of fault for oblique-slip gives percentage greater than 100).

CHAPTER 3: TECTONIC EXPLANATION

Since the end of the 19th century there has been debate as to the nature of the contact between the Franciscan Complex rocks and the Great Valley Group sediments. Since the acceptance of plate tectonics, there has been great debate as to the role of the Coast Range Fault and how blueschist facies metamorphic grade rocks, which formed at depths of 15-20 kilometers, came to be juxtaposed with oceanic crust and forearc sediments. Over 30 different studies have (discussed in previous sections) attempted to explain this relationship. Although there are many differences between models, two characteristics are the same. The first similarity is the existence of the Coast Range Fault and that it is responsible for the displacement between the Franciscan and Coast Range Ophiolite/Great Valley rocks. The second commonality is the steep upturned Great Valley Group, specifically the Knoxville Formation, dips eastward.

In the Stonyford area, Franciscan rocks are primarily lawsonite-bearing phyllitic rocks formed at approximately 15-20 kilometers depth and highly deformed (Jayko et al, 1986). The Coast Range Ophiolite is not exposed as a section of idealized continuous oceanic crust and upper mantle section. The Coast Range Ophiolite is highly disrupted, but the overlying Great Valley Group is just tilted.

This study presents fault slip kinematic analysis from six transects. Any tectonic explanation must account for the field evidence for movement. Another finding is the proportion of fault type (reverse, normal, left-lateral, etc.) is similar across all transects.

3.1 Pre-subduction

Nowhere near the Stonyford area is an intact ophiolite section preserved. If the Coast Range Ophiolite was simply rotated up to near vertical, then a transect from east to west should encounter volcanic, sheeted

dikes, massive gabbro, layered gabbro, then ultramafic rocks. Mafic volcanics and small amounts of chert were only observed along the Fouts Springs Transect (Figure 2.2). Shervais et al. (2005) reported gabbros present near Auk Auk Ridge, south of Black Diamond. Serpentinite outcrops were found in the eastern and western portions of all transects. Along the Goat Mountain Road, Fouts Springs, Mill Creek, North Fork Stony Creek, and Black Diamond Transects, the serpentinites formed a contact with Franciscan rocks. At the Fouts Springs Transect serpentinites formed a contact with mafic rocks. Along the Goat Mountain Road and County Road 309 Transects, serpentinites formed contacts with the Knoxville Formation.

3.1.1 Previous studies on serpentinite mélange formation

Saleeby (1984) argued that serpentinite mélanges should be common along oceanic transform margin fracture zones. Oceanic transform margins produce disrupted segments of oceanic crust that are perpendicular to spreading ridges. These fracture zones are a conduit allowing ocean water to reach upper mantle depths and cause serpentinization. The decrease in density leads to diapirism causing a solid state insertion of serpentinite into the overlying mafic oceanic crust while faulting is active. In the process, sections of oceanic crust become mixed within the fracture zones. Transform zones would be areas of oceanic crust and serpentinized mantle that were broken and mixed before subduction began.

Shervais et al. (2011) proposed serpentinite mélanges can also form within a subduction zone, mixing rocks from the upper and lower plates. They proposed that both processes occurred to make the serpentinite mélange near Stonyford. They believed that the Franciscan subduction zone nucleated along a transform margin fracture zone producing additional disruption. The two deformation events produced a zone of serpentinite matrix mélange. They also concluded that serpentinite mélange originated by

hydrating the upper mantle with later shear deformation caused by volume expansion. Lithologies were mixed when the lower plate initially subducted beneath the upper plate.

3.1.2 Summary

The Coast Range Ophiolite is highly broken up with 100s to 1,000s of meters of internal displacements. The Coast Range Ophiolite probably formed along a transform margin fracture zone where ocean waters were hydrothermally circulated serpentinizing the upper mantle peridotites concurrent with faulting. Serpentinite could be inserted through the fractures mixing sections of oceanic crust prior to subduction.

3.2 Syn-subduction

3.2.1 Subduction channel and underplating

Shreve and Cloos (1986), and Cloos and Shreve (1988 a,b) proposed a quantitative model for subduction zone mechanics. Their model consisted of a low-viscosity layer of sediments between the subducting slab and the overriding plate. They originated the idea of the subduction channel, in which most shear strain during convergence is concentrated. It is within the subduction channel that sediments can sometimes upwell to form shale-matrix *mélange*. Underplating occurs at depth when the top-most layers of sediments lose water and become compacted, increasing the shear strength and thus shear strain becomes concentrated in the underlying sediments. The top layers of sediments underplate as faults deactivate. These sediments undergo blueschist grade metamorphism (Figure 3.1) beneath the hanging wall. This process began after subduction initiated in the Franciscan at ~150 Ma. Over time the Franciscan accretionary prism widened by offscraping and thickening by underplating.

The Coast Range Fault, as evidenced by the overall map pattern primarily strikes north to south. However, near the Stonyford area the fault

forms an acute and an obtuse bend diverting from its typical north to south strike. The acute and obtuse geometry is mechanically consistent with right-lateral movement and could be explained by the oblique convergence of the Farallon Plate with the North American Plate (Figure 3.2). However, the obliquity was minor as few of the faults ($n = 35$) are strike-slip near Stonyford. Right-lateral faults constituted 2/3 of the strike-slip faults presented as data further minimizing the effects of oblique convergence. The Coast Range Ophiolite is poorly exposed near the acute bend and composed mostly of foliated serpentinite. As mentioned in previous sections, foliated serpentinites are more prone to erosion than massive serpentinite. Therefore, it is reasonable to conclude that the serpentinite mélange, which formed at a transform margin setting and then mixed with the overlying mafic rocks, was a zone of weakness before subduction began. After subduction initiation, material was underplated beneath the Coast Range Ophiolite. The subducted rocks reached peak metamorphic blueschist facies conditions. Underplating thickened the accretionary wedge and uplifted the ophiolite (Figure 3.1b). Overthickening eventually lead to seaward spreading and horizontal extension by normal faulting (Figure 3.1c) bringing the blueschists towards the surface as the mass of underplated and overlying ophiolite became thinner. Exhumation by normal faulting began after the Franciscan rocks reached peak metamorphic conditions (Figure 3.1d).

3.2.2 Exhumation

As underplating continues, the accretionary wedge thickens. Eventually the wedge over-steepens, and horizontal extension by normal faulting thins the overlying rocks. The blueschists near Stonyford were at depths of 15-20 km. Thinning the wedge by 1/3 would bring these blueschists

Figure 3.1. Franciscan subduction through time. (a) Early stage of underplating (~120 Ma). (b) Early stage of Coast Range Ophiolite and Great Valley Group rotation (~90 Ma). (c) Oversteepening leads to extension within accretionary prism (~60 Ma). (d) Normal faulting/erosion exhumes blueschist (~30 Ma).

Figure 3.2. Right-lateral oblique convergence of North American and Farallon Plates is compatible with the acute/obtuse bend in the Coast Range Ophiolite.

5 to 6 km closer to the surface (Figure 3.1). It is believed that exhumation was primarily accommodated by distributed normal faulting on faults with average spacing of 1 per 10 m. There is no evidence from the Goat Mountain Road exposure that the Coast Range Fault was a master fault with 15 to 20 kilometers of offset. Three kilometers of vertical displacement is the favored estimate for offset along the Coast Range Fault, but it could have been more or even less. The Coast Range Ophiolite is a series of normal faults with displacements concentrated in areas of serpentinite mélange. As underplating continues, the blocks of serpentinite between the normal faults become rotated. In the process, a steeply dipping normal fault that becomes rotated can end up with an orientation indicating reverse displacement (Figure 3.3). The Coast Range Ophiolite was highly disrupted prior to subduction. Thus, most movement was probably concentrated within the Coast Range Ophiolite as the Great Valley group was mostly just tilted as underplating drove the Franciscan upwards. In this scenario, most of the normal faulting within the Coast Range Ophiolite occurred as the western edge of the Great Valley Group simply tilted upward. Approximately 1,100 faults were recorded in the Stonyford area. An effective statistical representation for fault displacement is to normalize the six transects by dividing the number of faults measured by the number of transects and the length of exposure. Therefore, approximately 200 faults will be used in calculations. The average length of exposure along the six transects is approximately three kilometers. With an average fault spacing 1 per 10 meters, it is estimated that approximately 300 faults were not exposed in each transect. With an average displacement of only one meter along these faults, 500 meters of vertical offset was accommodated within the Coast Range Ophiolite. If the average was ten meters, then five kilometers of vertical offset was accommodated.

Figure 3.3. (a) Fault distribution within the Franciscan Complex and the Coast Range Ophiolite. (b) Steeply dipping normal fault that rotates 30° attains an orientation having reverse fault kinematics.

3.3 Post-subduction

At approximately 2 Ma, the Mendocino Triple Junction migrated northward past the Stonyford area, abruptly shutting off subduction. Hot asthenospheric mantle replaced the void that was previously occupied by the subducting Farallon plate, increasing the geothermal gradient causing isostatic uplift that increased the elevation of the California Coast Ranges by approximately one kilometer (Furlong, 1984). This elevation rise further increased the erosion rate and enhanced exhumation in the region. Ring and Brandon (1994) concluded that exhumation of the Franciscan was entirely due to erosion at a fast rate of 1 mm/yr (which requires 20 m.y. to expose the Eastern Belt metamorphic rocks). Therefore, two kilometers of erosional denudation seems plausible estimate within the Coast Ranges.

3.4 Conclusion

In the Stonyford area there is evidence for extension by normal faulting. Previous tectonic models that display the Coast Range Fault as a “thrust”, explain exhumation of lawsonite-bearing blueschist facies metamorphic rocks by relying entirely on erosion. These models do not account for the normal displacement within the Coast Range Ophiolite nor do they explain the near vertical orientation of the bedding of the Knoxville Formation.

A normal-type model in the manner of Platt (1986) explains how subduction brings materials to great depths and how underplating thickens and steepens the accretionary prism. However, this model shows the Coast Range Fault as a major fault with 15-20 kilometers of vertical offset without accounting for the faulting within the Coast Range Ophiolite.

The preferred model is that the lawsonite-bearing blueschist facies rocks were exhumed by 10 to 15 kilometers of extensional thinning driven by underplating associated with ~3 kilometers of vertical offset along the Coast

Range Fault, 1-5 kilometers of offset within the Coast Range Ophiolite, and ~2 kilometers from erosion. This would account for the ~15 kilometers of exhumation needed to unroof the blueschist rocks.

Appendix A

Fault Data

The following tables display all fault data collected in the field. Fault planes have been formatted into azimuthal right-hand rule with the dip direction 90° clockwise from strike. All lineations are reported as trend and plunge. Fault lengths are reported based on exposed length along the outcrop. The information below explains all abbreviations used in the tables.

Fault type	Symbol
Dip-slip	DS
Strike-slip	SS
Oblique-slip	OB

Dip-slip type	Symbol
Normal	N
Reverse	R

Strike-slip type	Symbol
Left-lateral	LL
Right-lateral	RL

Appendix B

Top 10 field trip localities

- 1 - Coast Range Fault
- 2 - Massive Serpentine
- 3 - Mafic volcanics/chert
- 4 - Serpentine matrix
mélange
- 5 - Foliated serpentinite/
Franciscan schist
- 6 - Franciscan slate
- 7 - Massive serpentinite
- 8 - Greenstone
- 9 - Coast Range Fault?
- 10 - Knoxville Formation

VITA

Scott Hoag was born on April 2, 1979 to Elmer and Carolyn Hoag in Lafayette, Louisiana. After graduating from Ovey Comeaux High School in 1997, he began studies at Louisiana State University. He graduated in 2001 with a Bachelor of Science degree in Business. In the summer of 2002, he joined the United States Marine Corp. In 2009, after his honorable service in the military, he matriculated to the University of Texas at Austin after completing the needed courses in chemistry, physics, and geology for a foundation. In 2010, he began graduate studies in pursuit of a degree in Geological Sciences.
